Background: There is little systematic research on the efficacy and tolerability of the addition of adjunctive analgesic agents in paravertebral analgesia. The addition of adjunctive analgesics, such as fentanyl and clonidine, to local anesthetics has been shown to enhance the quality and duration of sensory neural blockades, and decrease the dose of local anesthetic and supplemental analgesia.

Objectives: Investigation of the safety and the analgesic efficacy of adding 1 µg/kg dexmedetomidine to bupivacaine 0.25% in thoracic paravertebral blocks (PVB) in patients undergoing modified radical mastectomy.

Study Design: A randomized, double-blind trial.

Setting: Academic medical center.

Methods: Sixty American Society of Anesthesiologists physical status –I – III patients were randomly assigned to receive thoracic PVB with either 20 mL of bupivacaine 0.25% (Group B, n = 30), or 20 mL of bupivacaine 0.25% + 1 µg/kg dexmedetomidine (Group BD, n= 30). Assessment parameters included hemodynamics, sedation score, pain severity, time of first analgesics request, total analgesic consumption, and side effects in the first 48 hours.

Results: There was a significant reduction in pulse rate and diastolic blood pressure starting at 30 minutes in both groups, but more evidenced in group BD (P < 0.001). Intraoperative Systolic blood pressure showed a significant reduction at 30 minutes in both groups (P < 0.001) then returned to baseline level at 120 minutes in both groups. There was a significant increase in pulse rate starting 2 hours postoperative until 48 hours postoperatively in group B but only after 12 hours until 48 hours in group BD (P < 0.001). The time of the first rescue analgesic requirement was significantly prolonged in the group BD (8.16 ± 42 hours) in comparison to group B (6.48 ± 5.24 hours) (P = 0.04). The mean total consumption of intravenous tramadol rescue analgesia in the postanesthesia care unit in the first 48 hours postoperatively was significantly decreased in group BD (150.19 ± 76.98 mg) compared to group B (194.44 ± 63.91 mg) (P = 0.03). No significant serious adverse effects were recorded during the study.

Limitations: This study is limited by its sample size.

Conclusion: The addition of dexmedetomidine 1 µg/kg to bupivacaine 0.25% in thoracic PVB in patients undergoing modified radical mastectomy improves the quality and the duration of analgesia and also provides an analgesic sparing effect with no serious side effects.

Key words: Dexmedetomidine, paravertebral block, postoperative analgesia, breast cancer surgery
Breast cancer is perhaps the most common cancer in women that requires frequent surgery (1). Nearly 40% of postoperative breast surgery patients experience significant acute postoperative pain, with a pain score above 5 reflecting the inadequacy of conventional pain management (2). Most of the responses of the human body to postsurgical pain have been proven to be detrimental to the patient’s homeostasis and recovery. Moreover, the incidence of chronic postoperative pain in breast surgery patients is as high as 50% and inadequate analgesia is considered as an independent risk factor (3). Hence, a number of therapeutic measures have been accepted as a part of the “multi-modal” approach to postoperative pain control. Thoracic paravertebral block (PVB) is used for pain relief after thoracotomy (4,5) and mastectomy (6-9). PVB can provide profound, long-lasting sensory deafferentation. The resulting greater attenuation of surgical stress response may translate into reduced inotropic stimulation of the heart. Additionally, unlike general anesthesia, PVB can provide superior postoperative analgesia, less nausea and vomiting, shorter recovery time, require fewer analgesics, earlier mobilization, and earlier home readiness for discharge. The use of PVB in patients undergoing ambulatory breast surgery has a cost-saving potential (10). There is little systematic research on the efficacy and tolerability of the addition of an adjunctive analgesic agent in paravertebral analgesia. The addition of adjunctive analgesics, such as fentanyl and clonidine, to local anesthetics has been shown to enhance the quality and duration of sensory neural blockade, and decrease the dose of local anesthetic and supplemental analgesia (11).

Dexmedetomidine is a highly selective α2-adrenoeceptor agonist recently introduced to anesthesia; it produces a dose-dependent sedation, anxiolysis, and analgesia (involving spinal and supraspinal sites) without respiratory depression (12,13). α2-agonists are known to reduce anesthetic requirements, and because of their sympatholytic properties, they afford hemodynamic stability during the intraoperative period (14). Administration of an α2-agonist via an intrathecal or epidural route provides an analgesic effect in postoperative pain without severe sedation. This effect is due to the sparing of supraspinal central nervous system (CNS) sites from excessive drug exposure, resulting in robust analgesia without heavy sedation (15). The adverse effects of dexmedetomidine include hypotension, hypertension, nausea, bradycardia, atrial fibrillation, and hypoxia (16,17).

The aim of this study was to investigate the safety and the analgesic efficacy of adding 1 µg/kg dexmedetomidine to bupivacaine 0.25% in thoracic PVB in patients undergoing modified radical mastectomy.

Methods

This randomized, double-blind study was approved by the local ethics committee of South Egypt Cancer Institute, Assuit University, Assuit, Egypt. After written informed consent, 60 ASA I – III patients (aged 25-70 years, weight 50 – 85 kg) who were scheduled for elective modified radical mastectomy with axillary dissection were enrolled in the study. Patients with a known allergy to the study drugs, conduction abnormalities, bleeding diathesis, infection at the injection site, central neuropathy, liver or renal impairment, drug or alcohol abusers, and those with psychiatric illnesses that would interfere with perception and assessment of pain were excluded from the study. Preoperatively, patients were taught how to evaluate their own pain intensity using the Visual Analogue Scale (VAS). Scored from 0 to 10 (where 0 = no pain and 10 = the worst pain imaginable). Oral diazepam (5 mg) was taken the night before surgery. Upon arrival at the operating room a 16-gauge catheter was inserted intravenously in the dorsum of the hand; lactated ringer’s solution 10 mL/kg was infused intravenously over 10 minutes before the initiation of anesthesia. Basic monitoring probes (electrocardiography, noninvasive blood pressure, O2 saturation, and temperature) were applied. The patients were seated for placement of the block and were sedated with incremental intravenous doses of midazolam (1 – 3 mg) and fentanyl (50 – 100 µg). Thoracic PVB were then performed as described by Moore (18) and Katz (19). Intradermal lidocaine was used at the site of the needle insertion. The superior aspect of the spinous processes of T1 – T6 were marked. The skin entry points were 3 cm lateral to the marks. A 22-gauge quincke spinal needle attached through extension tubing to a syringe containing the study drugs was used. The needle was inserted perpendicular to the skin for a distance of 2 to 4 cm until the transverse process was contacted. The needle was withdrawn and walked cephalad off the transverse process and advanced for a further 1.5 to 2 cm. Patients were allocated into 2 groups of 30 patients each using a computer-generated random number assignment in sealed opaque envelopes. A staff anesthesiologist not involved in the management of the patient or the study prepared the injectate according to randomization. The patients and all staff involved in patient management...
and data collection were unaware of the group assignment. In group B, the bupivacaine group, patients received 20 mL of bupivacaine 0.25% paravertebrally, divided into 3 – 4 mL in each level. In group BD, the bupivacaine + dexmedetomidine group, patients received 20 mL of bupivacaine 0.25% + 1 µg/kg dexmedetomidine paravertebrally divided into 3 – 4 mL in each level. The time for performance of the block ranged from 10 to 15 minutes. The success of the block was tested by decrease pin prick sensation at the expected dermatomal level (from T1–T6). Immediately after the block, the patients were placed in the supine position. General anesthesia was induced by fentanyl 1.5 µg/kg, propofol 2 – 3 mg/kg, and lidocaine 1.5 mg/kg. Endotracheal intubation was facilitated by cisatracurium 0.15 mg/kg. Anesthesia was maintained by isoflurane 1 – 1.5 MAC. Fentanyl 0.5 µg/kg and cisatracurium 0.03 mg/kg were given when indicated. Patients were mechanically ventilated to maintain ETCO2 between 33 and 36 mmHg. Heart rate and systolic and diastolic blood pressures were recorded preoperatively and after 30 minutes, 60 minutes, and 120 minutes. Hypotension was defined as a 15% decrease in systolic blood pressure from the baseline. Bradycardia was defined as a heart rate slower than 50 beats per minute or as an inappropriately slow heart rate despite hypotension. Hypoxia was defined as an oxygen saturation value < 90%. Hypotension was treated with intravenous boluses of ephedrine 0.1 mg/kg and normal saline 5mL/kg, the same doses were repeated as required, bradycardia was treated with intravenous atropine 0.01 mg/kg. At the end of the operation patients were transferred to the postanesthesia care unit and were monitored for vital signs (heart rate, noninvasive blood pressure, respiratory rate, and saturation of peripheral oxygen). The level of sedation was recorded using a modified observer’s Assessment of Alertness/ Sedation Scale where 1 = awake/alert to 5 = sleep/unarousable. VAS at rest (VAS.R) and during movement or ipsilateral arm abduction (VAS.M) were assessed immediately postoperatively and at hours 2, 4, 6, 12, 24, 36, and 48 of the postoperative period. Intravenous tramadol 100 mg was given when the VAS was ≥ 3 or upon patient request. The time of the first request for analgesia and the total analgesic consumption in the first 48 hours were recorded. Postoperative adverse effects such as nausea, vomiting, hypotension, bradycardia, and cardiac arrhythmia were recorded and treated, also postoperative complications of the block such as accidental pneumothorax and vascular puncture were recorded and treated.

### Statistical Analysis

The power of the study was based on a calculated sample size of 30 patients which would have 80% power of detecting a difference at a 0.05 level of significance, using a confidence interval of 95%. Analysis was performed using SPSS version 17 (Chicago-USA). Data was presented as mean ± SD, numbers, and percentages. Repeated measures ANOVA was used to test the change of different parameters having normal distribution overtime in both study groups (time effect) and also to test the difference between group B and BD over time (group interaction). Bonferroni test was used for multiple pairwise comparisons. For VAS score, Friedman test was used to show effect of time in each study group. Pairwise comparisons were done using Wilcoxon rank test. P < 0.05 was considered significant.

### Results

There were no significant differences among the 2 groups in demographic data as regard to age, weight, height, BMI, and duration of surgery (P > 0.05) (Table 1). Regarding hemodynamic parameters measured during the intraoperative period, there was a significant reduction in pulse rate starting at 30 minutes in both groups, but more evidenced in group BD (P-value for group interaction < 0.001). Pulse rate became stable in group B until 120 minutes and started to rise but not to baseline rate in group BD (Table 2, Fig. 1). Intraoperative Systolic blood pressure showed a significant reduction at 30 minutes in both groups then returned to baseline level at 120 minutes in both groups (P-value for interaction < 0.001) (Table 3, Fig. 2). Changes in intraoperative diastolic blood pressure were similar to pulse rate where a significant drop occurred at 30 minutes, but more evidenced in group BD, then became stable until 120 minutes in group B and increased but not to baseline in group BD (Table 4, Fig. 3) (P-value for group interaction < 0.001). There was a significant increase in

Pulse rate starting 2 hours postoperative until 48 hours postoperatively in group B but only after 12 hours until 48 hours in group BD (P-value for group interaction = 0.001), (Table 5, Fig. 4). No significant changes were recorded in the 2 study groups in systolic and diastolic blood pressure measured during the postoperative period (P > 0.05). VAS.R score measured at resting did not show significant reduction in group BD but showed a significant reduction after 2 hours postoperative in group B then started to increase with no significant difference from baseline after 12 hours (Fig. 5). There was no significant changes in VAS.M in either study

group postoperative (Fig. 6). The time of the first rescue analgesic requirement was significantly prolonged in group BD (8.16 ± 42 hours) in comparison to group B (6.48 ± 5.24 hours) (P = 0.04) (Table 6). The mean total consumption of intravenous tramadol rescue analgesia in the postanesthesia care unit in the first 48 hours postoperatively was significantly lower in group BD (150.19 ± 76.98 mg) in comparison to group B (194.44 ± 63.91 mg) (P = 0.03) (Table 6). Regarding adverse effects noted in the first 48 hours postoperatively 3 patients in group B and 2 patients in group BD had postoperative nausea and vomiting (PONV). Pneumothorax occurred in one patient in group B, with a nonsignificant difference in the incidence of postoperative adverse effects noted between the 2 groups (P > 0.05) (Table 7). No hypotension, bradycardia, cardiac arrhythmia, or vascular puncture was recorded.

**DISCUSSION**

In this study, we have demonstrated that patients who received PVB with 0.25% bupivacaine and 1 µg/kg dexmedetomidine in addition to general anesthesia experienced superior postoperative analgesia, prolongation of the time to the first rescue analgesic requirement, and decreased mean total intravenous tramadol consumption as compared with PVB with 0.25% bupivacaine alone and general anesthesia in the first 48 hours after breast cancer surgery.

Burlacu et al (20) noted that paravertebral fentanyl and clonidine in combination with diluted levobupivacaine (0.05%) are effective analgesics as demonstrated by a significant decrease in supplemental postoperative morphine consumption. At the doses used, the addition of fentanyl is associated with nau-

Data are expressed as mean±SD.
sea and vomiting, and clonidine with arterial hypoten-
sion. A study by Buhuvaneswari et al (21) demonstrat-
ed that the rescue analgesic consumption as well as
cumulative pain scores at rest and on movement were
significantly lower in 0.25% bupivacaine + epineph-
rine with fentanyl and 0.5% bupivacaine groups. They
concluded that lower concentrations of bupivacaine
can be combined with fentanyl to achieve analgesic ef-
cicacy similar to bupivacaine at higher concentrations,
decreasing the risk of toxicity in PVB. Previous stud-
ies (22-24) report that multiple injections do improve
the duration and quality of analgesia, with a higher
probability of procedural complications. On the other
hand, a single injection provides more patient comfort
and lowers the need for sedation during performance
of PVB, thereby improving patient satisfaction (25,26).
Small doses of multiple injections are supposed to pro-
vide better consistency in the optimal spread of the
injectate (27). A few clinical studies have examined the
epidural usual dose of 1 – 2 µg/kg dexmedetomidine in
thoracic and upper abdominal surgery. Unsurprisingly,
epidural dexmedetomidine potentiates neuroaxial
local anesthetics, decreases intraoperative anesthetic
requirements, and improves postoperative analgesia
hence reducing pulmonary complications associated
with thoracotomy (28). Local anesthetic acts by block-
ing sodium channels, whereas an α2-adrenoceptor
agonist acts by binding to presynaptic C- fibers and
postsynaptic dorsal horn neurons; they produce anal-
gesia by depressing the release of C-fiber transmitters
and hyperpolarization of postsynaptic dorsal horn neu-
rons (29-33). On the other hand, Gupta et al (34) com-
pared the role of intrathecal dexmedetomidine and
fentanyl as adjuvants to bupivacaine, and concluded
that intrathecal dexmedetomidine is associated with
prolonged motor and sensory block, hemodynamic
stability, and reduced demand for rescue analgesics in
24 hours as compared to fentanyl. In another study,
Gupta et al (35) found that the addition of 5 µg of
dexmedetomidine to 3 mL 0.75% isobaric ropivacaine
intrathecally produced a prolongation in the duration
of the motor and sensory block in lower limb surger-
ies. Good acute pain relief is associated with a lower
risk of development of chronic pain in the operative
area (36). Kairaluoma et al (37) reported that preinci-
sional PVB provided good acute postoperative pain re-
lied and prevented pain conditions for up to one year
after breast cancer surgery. In our study, there were
no significant differences in sedation scores between
the 2 groups. Also our study showed that the addition
of 1 µg/kg dexmedetomidine to 0.25% bupivacaine in
PVB before induction of general anesthesia induced
significant reduction in pulse rate and systolic blood
pressure at 30 minutes intraoperatively, also diastolic
blood pressure showed a significant reduction at 30
minutes intraoperatively. In the postoperative period
systolic and diastolic blood pressure showed no sig-
nificant difference between the 2 groups, but heart
rate significantly increased 12 hours postoperatively
until 48 hours in the dexmedetomidine + bupivacaine
group. Burlacu et al (20) found that when they ad-
ministered 150 µg clonidine followed by an infusion
of levobupivacaine 0.05% with clonidine 3 µg.mL-1
in PVB systolic blood pressure at any measured time
interval was significantly lower in the levobupivacaine
+ clonidine group when compared with other groups.
Also the number of patients experiencing bradycardia
(heart rate < 50 beats/min.) over the 24 hours was 2
(16.6%) in this group. In our study only 3 patients in
group B and 2 patients in group BD developed PONV
and were treated by antiemetic. Pneumothorax oc-
curred only in one patient in group B and was man-
aged. No patients suffered hypotension, bradycardia,
cardiac arrhythmia, or vascular puncture.

**Conclusion**

In conclusion, the addition of dexmedetomidine 1
µg/kg to bupivacaine 0.25% in thoracic PVB in patients
undergoing modified radical mastectomy improves
the quality and the duration of analgesia and also
provides an analgesic sparing effect with no serious
side effects.
