A SYSTEMATIC REVIEW OF DIAGNOSTIC UTILITY OF SELECTIVE NERVE ROOT BLOCKS

Clifford R. Everett, MD, Rinoo V. Shah, MD, Nalini Sehgal, MD, and Anne Marie McKenzie-Brown, MD

Background: Transforaminal epidural injections, or selective nerve root blocks, are used for a myriad of different spinal disorders. A clear consensus on the use of selective nerve root injections as a diagnostic tool does not currently exist. Additionally, the effectiveness of this procedure as a diagnostic tool is not clear.

Objective: The objective was to evaluate the accuracy of selective nerve root injections in diagnosing spinal disorders.

Study Design: The study involved a systematic review of diagnostic studies about selective nerve root blocks for the diagnosis of spinal pain.

Methods: A systematic review of the literature for clinical studies was performed to assess the accuracy of selective nerve root injections in diagnosing spinal disorders. Methodologic quality evaluation was performed utilizing AHRQ and QUADAS criteria. The methodology of the studies was graded and the evidence was classified into five levels: conclusive, strong, moderate, limited, or indeterminate.

Results: There is limited evidence on the effectiveness of selective nerve root injections as a diagnostic tool in spinal disorder. There is insufficient research into this area for strong support, but the available literature is supportive of selective nerve root injections as a diagnostic test in equivocal radicular pain. The current analysis provides moderate evidence of transforaminal epidural injections in the preoperative evaluation of patients with negative or inconclusive imaging studies.

Conclusions: Selective nerve root injections may be helpful as a diagnostic addition in evaluating spinal disorders with radicular features, but the role of this diagnostic test needs to be further clarified by additional research and consensus on technique.

Keywords: Selective nerve root block, transforaminal epidural injection, spinal pain, discogenic pain, radiculopathy, nerve root pain

Pain that originates from the spine is frequently difficult to specifically diagnose as imaging abnormalities are frequently found in people without pain (1, 2). Excluding fractures, disorders of the human spine that produce pain, can be categorized as compressive, inflammatory, degenerative, or multifactorial combination.

For a structure to be painful it must have a nerve supply. It also must be capable of producing the pain described clinically. The structure must also be susceptible to disease or injury. For the structures that meet these criteria it is important to determine if this is the cause of the individuals’ pain and treat it appropriately.

Methods have been developed to test painful structures using fluoroscopic (x-ray) guided injections of anesthetics. If a structure is selectively anesthetized and the individual describes pain relief for the duration of the anesthetic medication, that structure is determined to be the source of pain (3). For compressive and inflammatory disorders of spinal nerve roots, the common area for this to occur is within the bony channel created between adjacent vertebrae named the neural foramen.

Spinal injections have received considerable study and interest in regards to therapeutic effect. Specifically, the use of epidural steroid injections in the treatment of spinal disorders has progressed as the procedures have become more exact with the aid of fluoroscopic or CT guidance. The indications have increased from radicular pain, to spinal stenosis, and lower back pain related to a discogenic cause (4-18). The use of specific foraminal and nerve root injections as a diagnostic tool does not have a consistent method of application or medication. In present literature, selective nerve root block (old nomenclature) or transforaminal epidural injection (modern nomenclature) consists of injection of contrast, local anesthetic, or other substances around spinal nerves under fluoroscopy. Some injectors use anesthetic alone; others use a smaller steroid dose, arguing that the steroid should not have an immediate response. The volumes used in the injection also vary by physician with some using a standard volume, and others using a volume consistent with the amount necessary to reach the lateral recess. Purists insist on describing them as two separate and distinct techniques. Over the years, authors have used them interchangeably. Despite the variance in practice, the technique holds promise as a diagnostic tool, but the reliability is unclear (17, 22-24).

The value of provocative and analgesic spinal injections was recognized in 1938 by Steindler and Luck (22). MacNab (23) in 1971 demonstrated the value of diagnostic, selective nerve root blocks in the preoperative evaluation of patients with negative or inconclusive imaging studies and clinical findings of nerve root irritation. Since then, nerve blocks have been used to diagnose the source of radicular pain when imaging studies suggested possible compression of several nerve roots (24-33). The relief of usual symptoms following the injection of local anesthetic (1 ml of 2% Xylocaine) is considered as the essential determinate for diag-
nostic information. In 1992, Nachemson (34) analyzed the literature on low back pain and indicated that diagnostic, selective nerve root blocks provided important prognostic information about surgical outcomes. Van Akkerveeken (31) described the sensitivity, specificity, and predictive value for diagnostic, selective nerve root blocks. He also showed that for a block to be determined positive, it required concurrent symptom reproduction during root stimulation and full relief of pain following anesthetic infusion. However, transforaminal epidural or selective nerve root injection as a diagnostic entity is a controversial issue.

This systematic review was performed to determine if selective nerve root injections are an effective method for diagnosing spinal disorders.

Methods

Inclusion Criteria

Types of Studies

Included in the analysis were controlled and uncontrolled clinical studies with diagnostic selective nerve root injections as a part of the study design.

Types of Participants

Subjects with pain of spinal origin

Types of Interventions

Selective nerve root injections performed under fluoroscopic guidance

Types of Outcome Measures

Pain relief, correlation with other diagnostic tests or therapeutic outcomes

Exclusion Criteria

Types of Studies

Non-clinical studies, expert opinion, or clear therapeutic studies

Types of Interventions

Non-selective nerve injections, with the route of administration not specifically described, were assumed to be interlaminar and for the purposes of this review, were rejected.

Search Strategy

Relevant clinical trials meeting the inclusion criteria for this review were identified in the following manner:

1. A computerized database search was performed of MEDLINE (1966-September 2004), CINAHL - Cumulative Index to Nursing & Allied Health Literature, EMBASE, EBM - Evidence Based Medicine Reviews (Cochrane Database and Cochrane Central Register of Controlled Trials). Specific search terms used to capture the greatest number of applicable studies were: Diagnostic techniques & procedures, nerve root block Injections, and Spine. Facet joints and zygapophyseal were specifically excluded from the search. Included were English-only articles, or foreign language articles with an available English translation.

2. A review of the reference sections of the articles selected was also performed to identify potential additional studies for inclusion.

Method of Review

The computerized database search including the author, title, keywords, and abstract was printed and reviewed for exclusion criteria. If no clear exclusion criteria were identified within the abstract, the full journal article was obtained for review. The articles were reviewed by three physician reviewers. Articles were then abstracted for specific information on study design, number of patients, outcome studied, duration of study, and quality of study.

Methodological Quality

Quality of each individual article was evaluated by AHRQ (35) and QUADAS (36) criteria as shown in Tables 1 and 2.

Strength of Evidence

The level of evidence was evaluated as shown in Table 3.

Results

Literature Search

The database search yielded 258 articles which were reviewed for inclusion or exclusion. For articles excluded, specific reasons were documented in the database article log. Of the 258 articles found during the search, seven were selected for review and abstracting.

Methodological Quality

Multiple articles were excluded as they were clinical outcome studies and not diagnostic studies (4-11, 13, 37-40). Reference lists for the selected articles were reviewed and yielded an additional eight articles. A total of 11 articles were selected for study (Fig. 1) The 11 available studies are outlined in (Table 4) (25-28, 31, 32, 41-45).

Rationale

In general, imaging studies can accurately demonstrate disc herniation or nerve root compression. However, it is necessary to differentiate symptomatic from asymptomatic levels of nerve compression in cases of multiple sites or levels of involvement, or in situations of confounding clinical features. The underlying

principle of selective nerve root local anesthetic injection is the premise that a local anesthetic will act only locally at the site of nerve root pain generation. Consequently it is presumed that any systematic effect of a local anesthetic diminishing specificity of such a block is minimal. In addition, it also has been reported that anesthetic block distal to the site of nerve compression, as in a sciatic nerve block for nerve root compression, can, in fact, result in reduction of pain equal to nerve root

Adapted from ref. 16
Principles

Transformaminal epidural steroid injections or selective nerve root blocks can be performed in order to test the hypothesis that a target nerve root is the source of a patient's pain. Selective nerve root block must be performed under fluoroscopic visualization utilizing a low volume local anesthetic of 0.5-1 ml. If the pain is not relieved, the nerve root cannot be considered as transmitting the pain. However, if the pain is completely relieved with a properly performed block without leakage into surrounding structures, the nerve root is considered as the source of the pain. As for facet joint block or sacroiliac joint blocks, and provocative discography, no standards have been established to eliminate false positive responses with transformaminal epidural injections (16, 17). However, true-positive responses may be secured by performing controlled blocks with placebo injections of normal saline. Comparative local anesthetic blocks which have been shown to be valid in the diagnosis of facet joint pain have not been studied for transformaminal usage.

Validity

Transformaminal epidurals or selective nerve root blocks have been shown to have face validity. Local anesthetic injected accurately onto the correct target point of the nerve root selectively infiltrates the target nerve, and may provide the validity. Thus, performing the procedure with low volume local anesthetic under fluoroscopic visualization and limiting the injection onto the target nerve will preserve the face validity. However, the construct validity of selective nerve root blocks has not been established. Thus, it is not known in every individual case, whether the response is a true positive or not. Significant false positive rates have been described with multiple other diagnostic interventional techniques (16).

In addition to the false positive result, multiple confounding factors of psychological issues and sedation have not been studied for selective nerve root blocks.

Criterion

Even though results of biopsy or autopsy are not available to confirm specificity and sensitivity of selective nerve root blocks, surgical confirmation and clini-

Pain Physician Vol. 8, No. 2, 2005
cal results provide a reliable gold standard (27, 32, 44, 46, 49).

Haukis et al. (27) in an early study on patients with post-laminectomy radicular symptoms compared the diagnostic accuracy of spinal nerve root injections with Xylocaine to myelogram for surgical pathology and outcome. Of the 105 patients studied with selective nerve root injections, 55 underwent surgical re-explo-ration. Selective nerve root injections were accurate in making a diagnosis consistent with surgical pathology in 43 out of the 55 patients, or 93%; myelogram was accurate in 24%. The surgical outcome at an average of 20 months was improvement in 73% of the patients. They concluded that, in patients with surgically altered anatomy, selective nerve root block are helpful in making an accurate diagnosis.

Herron (32) examined the response to selective nerve root blocks as a means to assure spinal origin for the pain complaint. The surgical outcomes were as expected with patients having the best outcome for lumbar disc herniation and spinal stenosis and doing poorly with a history of prior surgery. The response to injection was helpful in narrowing potential surgical patients from 215 to 71 patients who subsequently underwent surgical repair.

Tajima (26), in an early study of this technique, compared the response for 106 patients to mechanical stimulation and anesthetic response to myelogram and surgical outcome. Comparison to the normal dye patterns in reference patients and cadaveric dye patterns was also attempted to clarify the role of radiographs as a diagnostic imaging tool. The disorders studied were diverse but selective nerve root block was helpful in determining the painful level in the majority of patients with corresponding abnormalities found on surgical repair. Additionally it was helpful in limiting the surgical de- compression to the area of primary pain generation.

Anderberg et al. (45) performed a prospective study on 20 patients with cervical selective nerve root blocks and a comparison of post surgical response. Of the 20 patients studied, 18 had a positive cervical selective nerve root block that corresponded to MRI findings, and complete post surgical pain relief.

**Accuracy**

Accuracy of any test is measured by sensitivity and specificity. Specificity is a relative measure of the prevalence of false-positives, whereas sensitivity is the relative prevalence of false-negative results. There are multiple confounding factors with selective nerve root blocks that may lead to a false positive result in spite of precautions. There are also numerous structures in close proximity that could also affect a false-positive block. Consequently, selective nerve root blocks are considered to have an excessively high level of sensitivity with a moderate or low level of specificity. As compared with sciatic nerve, posterior ramus block, or subcutaneous injection, a selective nerve root block in patients with sciatica has shown to have high specificity (41), however, the specificity was judged to be only moderate. In fact the specificity of sciatic nerve block was as good as or equal to a selective nerve root block (41).

The sensitivity and specificity of diagnostic nerve root block ranges from 45-100% (24, 25, 28, 31, 44). Schutz et al. (24) reported finding a corroborative lesion at the time of surgery in 87% of patients with a positive diagnostic block. Krempen and Smith (25) reported 100% surgical confirmation following a positive block. Dooley et al. (28) reported three out of 51 blocks to be false positive, providing a specificity of 94%. Stanley et al. (44) reported a 95% specificity. Van Akkerveeken (31) attempted to establish the diagnostic value of selective nerve root injections. In 37 patients with confirmed lumbar radiculopathy, compared to nine patients with pain due to metastases, it was found that the sensitivity for determining pain of spinal neural origin was 100%. The specificity was studied by comparison to a normal level on imaging and exam with a selective nerve root block, and was 90%. Of the 37 patients with lumbar radiculopathy, some declined surgery. The predictive value for a good outcome was determined with, and without, the patients who did not want surgery. If all patients who declined surgery were included in the analysis as surgical failures, the positive predictive value of a good surgical outcome with a positive selective nerve root block was 70%. The positive predictive value was 95% when patients who had surgery were the only ones included in the analysis. Within this study, selective nerve root injections were a highly sensitive, specific test with high predictive value for surgical outcome.

Anderberg et al. (45) reported 96% specificity. Haueisen et al. (27) reported 93% specificity. Dooley et al. (28) reported 85% specificity.

**Diagnostic Validity**

Diagnostic selective nerve root injection is typically performed in a patient with persistent pain when their history, examination, imaging and other precision diagnostic injections and electrophysiology testing do not clarify the pain generator. Kikuchi et al. (30) estimated that 20% of patients presenting with radicular pain required diagnostic nerve root blocks. Derby et al. (49) reported that patients who failed to obtain sustained radicular pain relief following the transforaminal blocks were less likely to benefit from subsequent surgical intervention. Manchikanti et al. (3), in exploring the role of transforaminal epidural injections in the diagnosis of low back pain of undetermined origin, performed transforaminal epidural injections in 35 patients, in a cohort of 120 patients. Of the 35 patients undergoing transforaminal epidural injections, 16 responded with pain relief. Herron (32) found the procedure useful in identifying previously undocumented disc herniations, the symptomatic level in multi-disc herniation, the primary pain generator in the spine-hip syndrome, previously undocumented root irritation and spondylolisthesis, the symptomatic level in multi-level stenosis, and the symptomatic route in patients with documented post operative fibrosis. White (50) supported the use of diagnostic selective nerve root blocks as a pre-surgical test in patients with equivocal anatomic finds. Pang et al. (51) utilizing application of spinal pain mapping in the diagnosis of low back pain in 104 cases, reported that lumbar nerve root involvement was noted in 44% of the patients.

**Methodological Quality**

Methodological Quality of these articles was judged by the criteria described by AHRQ (35) as well as QUADAS (36) as shown in Tables 1 and 2. The criteria and description of studies are shown in Table 4.
Strength of Evidence

Based on the review of all available studies, there is strong evidence that nerve root pain may be relieved with an appropriately performed selective nerve root block. However, based on the review of all the evaluations, the current analysis provides limited evidence of transforaminal epidural injections as a diagnostic tool for spinal disorders. The current analysis also provides moderate evidence for transforaminal epidural injections in the preoperative evaluation of patients with negative or inconclusive imaging studies, but with clinical findings of nerve root irritation.

DISCUSSION

This systematic review of the literature pertaining to selective nerve root blocks, or transforaminal epidural injections shows that the sensitivity and specificity of selective nerve root block ranges from 45-100%. Consequently, diagnostic selective nerve root block may be considered as an effective technique in evaluating patients with multilevel pathology to ascertain which level is the pain generator. Similarly, it may also be useful when the location of symptoms seems to conflict with abnormalities identified with imaging findings. Selective nerve root blocks also have been supported as a presurgical test in patients with equivocal anatomical findings. Further, they were found to be useful in identifying previous undocumented disc herniation. They are helpful in determining the symptomatic level in multilevel disc herniation, the primary pain generator in the spine-hip syndrome, previous undocumented root irritation and spondylolisthesis, the symptomatic level in multilevel stenosis, and the symptomatic route in patients with documented postoperative fibrosis. Prevalence of nerve root pain has been reported to be 44% in one study (51) in patients with low back pain of undetermined etiology after medical history, physical examination, radiographic examination, and electrophysiologic examination.

The severe limitations of our evaluation include the methodological quality of the studies available at present. The evaluation shows conflicting results, while proponents show good sensitivity and specificity. Others (41) indicate caution and also reveal that the sensitivity of nerve root block is very high whereas its specificity is only moderate. In fact the specificity of sciatic nerve block was as good as a selective nerve root block. However, the sensitivity of selective nerve root block was high when compared to sciatic nerve block, posterior ramus block, and subcutaneous injection in a cohort of patients with sciatica (41).

In contrast to facet joint blocks, the diagnostic selective nerve root blocks have been confirmed with surgical confirmation apart from clinical results. However, the specific limitations for intervention techniques also extend to transforaminal epidural injections. Further, transforaminal epidurals lack a proven methodology to avoid false positives. Utilizing the pain relief in a given patient as a standard can be neither confirmed nor denied. As a result, in terms of specificity and sensitivity, the true accuracy of transforaminal epidural steroid injections based on pain relieving phenomenon is uncertain. Further, transforaminal epidural injections are more similar to physical examination than most laboratory tests used in clinical medicine, which, because a diagnostic confirmation can be accomplished, can have an absolute gold standard for comparison to determine their true accuracy. Saal suggested their results should be considered in the light of inaccuracies present in all diagnostic tests in medicine. Clinicians can use this perspective to appropriately prioritize the data from these tests along with the earlier clinical data gathered sequentially from history, physical examination, and noninterventional imaging studies. With this information in hand, the clinician and patient can choose appropriate therapies for the given painful spinal disorder (17, 52-55).

There have been no systematic reviews to compare our results of the past reviews. However, Manchikanti et al (16) in preparation of guidelines for intervention techniques, summarized the evidence for transforaminal epidurals as moderate in the preoperative evaluation of patients with negative or inconclusive imaging studies, but with clinical findings of nerve root irritation. In the present review we have utilized all the studies utilized by Manchikanti et al (16) and also further literature available since then.

The inability of the physician to provide appropriate and accurate diagnosis for a patient with chronic spinal pain is frustrating not only for the patient but also the physician. Without clearcut findings from physical examination, history, radiologic evaluation, electrophysiologic examination, and psychological evaluation, once facet joint pain and discogenic pain is ruled out, the diagnostic transforaminal epidural injection is the only alternative left. They are also helpful in multiple conditions as described earlier.

CONCLUSION

There is moderate evidence as to the effectiveness of selective nerve root injections as a diagnostic tool in spinal disorders with radicular complaints. There is limited research into this area, but the available literature is supportive of selective nerve root injections as a diagnostic test in equivocal radicular pain. Additional research is necessary into the role of selective nerve root injections as a diagnostic tool in spinal disorders. Further research is necessary to determine the accuracy of selective nerve root blocks in determining surgical and non-surgical treatment outcomes compared to other established diagnostic imaging and electrodagnostic tests.
